Description

The IRS21571D is a fully integrated, fully protected 600V ballast control IC designed to drive virtually all types of rapid start fluorescent lamp ballasts. Externally programmable features such as preheat time and frequency, ignition ramp characteristics, and running mode operating frequency provide a high degree of flexibility for the ballast design engineer. Comprehensive thermal overload, or lamp failure during normal operation, as well as an automatic restart function, have been included in the design. The heart of this control IC is a variable frequency, 50% duty cycle oscillator with externally programmable deadtime. An integrated bootstrap MOSFET is also included to supply the high-side gate drive circuitry. The IRS21571D is available in 16 pin narrow body SOIC package.

Qualification Information[†]

Qualification Level		Industrial ^{††}	
		Comments: This family of ICs has passed JEDEC's Industrial qualification. IR's Consumer qualification level is granted by extension of the higher Industrial level.	
Moisture Sensitivity Level		SOIC16N	MSL2 ^{†††} (per IPC/JEDEC J-STD-020)
ESD	Machine Model	Class C (per JEDEC standard EIA/JESD22-A115)	
	Human Body Model	Class 3A (per EIA/JEDEC standard JESD22-A114)	
IC Latch-Up Test		Class , Level A (per JESD78)	
RoHS Compliant		Yes	

† Qualification standards can be found at International Rectifier's web site <http://www.irf.com/>

†† Higher qualification ratings may be available should the user have such requirements. Please contact your International Rectifier sales representative for further information.

††† Higher MSL ratings may be available for the specific package types listed here. Please contact your International Rectifier sales representative for further information.

Absolute Maximum Ratings

Absolute Maximum Ratings indicate sustained limits beyond which damage to the device may occur. All voltage parameters are absolute voltages referenced to COM, all currents are defined positive into any lead. The Thermal Resistance and Power Dissipation ratings are measured under board mounted and still air conditions.

Symbol	Definition	Min.	Max.	Units
V _B	High Side Floating Supply Voltage	-0.3	625	V

I_{RPH}	R_{PH} Pin Current ††	0	450	μ A
I_{RUN}	RUN Pin Current ††	0	450	μ A
I_{SD}	Shutdown Pin Current	-1	1	mA
I_{CS}	Current Sense Pin Current	-1	1	mA
T_J	Junction Temperature	-40	125	$^{\circ}$ C

† Enough current should be supplied into the VCC pin to keep the internal 15.6V zener clamp diode on this pin regulating its voltage.

†† Due to the fact that the RT input is a voltage-controlled current source, the total RT pin current is sum of all of the parallel current sources connected to that pin. For optimum oscillator current mirror performance, this total current should be kept between 50 μ A and 500 μ A. During the preheat mode, the total current flowing out of the RT pin consists of the RPH pin current plus the current due to the RT resistor. During the run mode, the total RT pin current consists of the RUN pin current plus the the current due to the RT resistor.

Electrical Characteristics

Application Information and Additional Details

Supply Bypassing and PCB Layout Rules

Component selection and placement on the pc board is extremely important when using power control ICs. V_{CC} should be bypassed to COM as close to the IC terminals as possible with a low ESR/ESL capacitor, as shown in Figure 1 below.

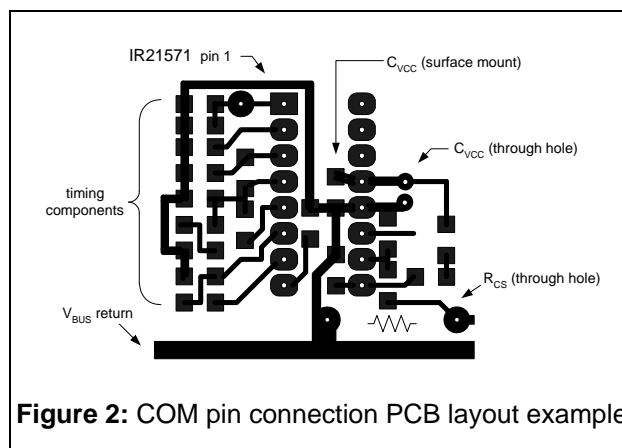

A rule of thumb for the value of this bypass capacitor is to keep its minimum value at least 2500 times the value of the total input capacitance (C_{iss}) of the power transistors being driven. This decoupling capacitor can be split between a higher valued electrolytic type and a lower valued ceramic type connected in parallel, although a good quality electrolytic (e.g., $10\mu F$) placed immediately adjacent to the VCC and COM terminals will work well.

In a typical application circuit, the supply voltage to the IC is normally derived by means of a high value startup resistor ($1/4W$) from the rectified line voltage, in combination with a charge pump from the output of the half-bridge. With this type of supply arrangement, the internal $15.6V$ zener clamp diode from VCC to COM will determine the steady state IC supply voltage.

Connecting the IC Ground (COM) to the Power Ground

Both the low power control circuitry and low side gate driver output stage grounds return to this pin within the IC. The COM pin should be connected to the bottom terminal of the current sense resistor in the source of the low side power MOSFET using an individual pc board trace, as shown in Figure 2. In addition, the ground return path of the timing components and V_{CC} decoupling capacitor should be connected directly to the IC COM pin, and not via separate traces or jumpers to other ground traces on the board.

These connection techniques prevent high current ground loops from interfering with sensitive timing component operation, and allows the entire control circuit to reject common-mode noise due to output switching.

The Control Sequence and Timing Component Selection

The IRS21571D uses the following control sequence (Figure 3) to drive rapid start fluorescent lamps.

Figure 3: IRS21571D Control sequence

The control sequence used in the IRS21571D allows the **Run Mode** operating frequency of the ballast to be higher than the ignition frequency (i.e., $f_{start} > f_{ph} > f_{run} > f_{ign}$). This control sequence is recommended for lamp types where the ignition frequency is too close to the run frequency to ensure proper lamp striking for all production resonant LC component tolerances (please note that it is possible to use the IRS21571D in systems where $f_{start} > f_{ph} > f_{ign} > f_{run}$, simply by leaving the RUN pin open).

Six pins in the IC are used to control the **Startup, Preheat, Ignition Ramp, and Run** modes of operation, and to allow ballast and lamp engineers the flexibility to optimize their designs for virtually any lamp type.

The heart of this controller is an oscillator which resembles those found in many popular PWM voltage regulator ICs. In its simplest form, this oscillator consists of a timing resistor and capacitor connected to ground. The voltage across the timing capacitor C_T is a sawtooth, where the rising portion of the ramp is determined by the current in the R_T pin, and the falling portion of the ramp is determined by an external deadtime resistor R_{DT} . The oscillograph in Figure 4 illustrates the relationship between the oscillator capacitor waveform and the gate driver outputs.

The deadtime can be programmed by means of the external R_{DT} resistor, given a certain range of C_T capacitor values, using the graph shown in Figure 5.

The R_T input is a voltage-controlled current source, where the voltage is regulated to be approximately 2.0V. In order to maintain proper linearity between the R_T pin current and the C_T capacitor charging current, the value of the R_T pin current should be kept between 50 μ A and 500 μ A. The R_T pin can also be used as a feedback point for closed loop control.

During the **Startup Mode**, the operating frequency is determined by the parallel combination of R_{PH} and R_T , combined with the values of C_T and R_{DT} , and the voltage at the R_T pin, as shown in Figure 6. The voltage at the R_T pin starts at an initial value above 2V, causing the initial start frequency to be higher than the preheat frequency. This frequency is high enough to ensure that the instantaneous voltage across the lamp during the first few cycles of operation does not exceed the strike potential of the lamp. As the voltage at the R_T pin decreases to the final value of 2V, the output frequency ramps down to the preheat frequency.

Figure 6: Oscillator section block diagram with external component connection

During the **Preheat Mode**, the operating frequency is determined by the parallel combination of R_{PH} and R_T , combined with the value of C_T and R_{DT} . This frequency, along with the **Preheat Time**, is normally chosen to ensure that adequate heating of the lamp filaments occurs. Typically, a 4.5:1 ratio of the hot filament-to-cold filament resistance is desired for maximum lamp life, as shown in Figure 7 below

The **Preheat Time** is programmed by means of the preheat capacitor, C_{PH} , an internal $1\mu A$ current source, and an internal threshold on the CPH pin of 4.0V, according to the following formula:

$$t_{PH} = 4E6 \cdot C_{PH}, \quad \text{or}$$

$$C_{PH} = 250E-9 \cdot t_{PH}$$

At the end of the **Preheat Time**, the internal, open-drain transistor holding the RPH pin to ground turns off, and the voltage on this pin charges exponentially up to the R_T pin potential. During this **Ignition Ramp Mode**, the output frequency exponentially decays to a minimum value. The rate of decay of this frequency is a function of the $R_{PH} * C_{RAMP}$ time constant. Because the **Ignition Ramp Mode** ends when the voltage on the CPH pin reaches 5.15V, the **Ignition Ramp Mode** is always 1/4th as long as the preheat time.

When the CPH pin reaches 5.15V, an open-drain transistor on the RUN pin turns on, and the external R_{RUN} resistor is then in parallel with the R_T resistor. The **Run Mode** operating frequency is therefore a function of the parallel combination of R_{RUN} and R_T , and this means that the operating power of the lamp can be programmed by means of R_{RUN} .

The following graphs, Figures 8 and 9, illustrate the relationship between the effective R_T resistance (i.e., the parallel combination of resistors which programs the C_T capacitor charging current) and the operating frequency.

Figure 8: f_{OSC} versus effective R_T
($t_{DEAD} = 2.0 \mu\text{sec}$)

Figure 9: f_{OSC} versus effective R_T
($t_{DEAD} = 1.0 \mu\text{sec}$)

Lamp Protection & Automatic Restart Circuitry Operation

Four pins on the IRS21571D are used for protection, as shown in Figure 10 below. These are VDC (dc bus monitor), SD (unlatched shutdown), CS (latched shutdown) and OC (CS+ threshold programming).

Figure 10: Lamp Protection & Automatic Restart circuitry block diagram with external component connection

Sensing The DC Bus Voltage

The first of these protection pins senses the voltage on the DC bus by means of an external resistor divider and an internal comparator with hysteresis.

When power is first supplied to the IC at system startup, 3 conditions are required before oscillation is initiated: 1.) the voltage on the VCC pin must exceed the rising undervoltage lockout threshold (12.5V), 2.) the voltage at the VDC pin must exceed 5.1V, and 3.) the voltage on the SD pin must be below approximately 1.85V. If a low dc bus condition occurs during normal operation, or if power to the ballast is shut off, the dc bus will collapse prior to the VCC of the chip (assuming the VCC is derived from a charge pump off of the output of the half-bridge). In this case, the voltage on the VDC pin will shut the oscillator off, thereby protecting the power transistors from potentially hazardous hard switching. Approximately 2V of hysteresis has been designed into the internal comparator sensing the VDC pin, in order to account for variations in the dc bus voltage under varying load conditions. When the dc bus recovers, the chip restarts from the beginning of the control sequence, as shown in timing diagram Figure 11 below.

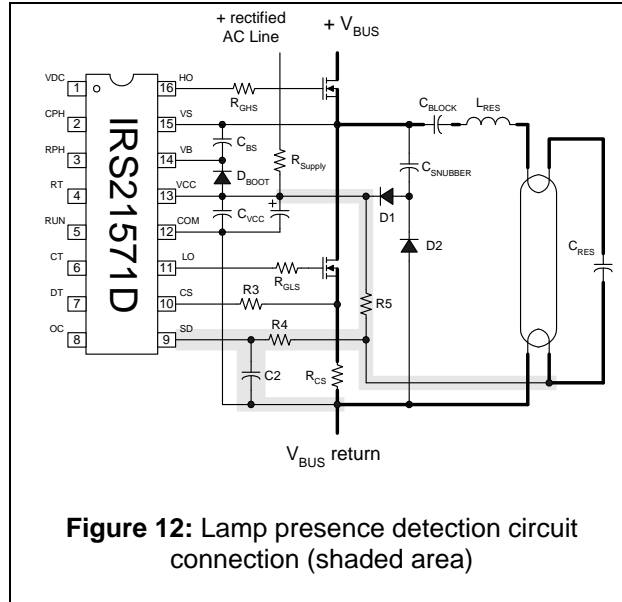

Figure 11: VDC pin fault and auto restart

Lamp Presence Detection and Automatic Restart

The second protection pin, SD, is used for both unlatched shutdown and automatic restart functions. The SD pin would normally be connected to an external circuit which senses the presence of the lamp (or lamps). A example circuit for a single lamp is shown in Figure 12.

When the SD pin exceeds 2.0V (approximately 150mV of hysteresis is included to increase noise immunity), signaling either a lamp fault or lamp removal, the oscillator is disabled, both gate driver outputs are pulled low, and the chip is put into the micropower mode. Since a lamp fault would normally lead to a lamp exchange, when a new lamp is inserted into the fixture, the SD pin would be pulled back to near the ground potential. Under these conditions a reset signal would restart the chip from the beginning of the control sequence, as shown in the timing diagram in Figure 13.

Thus, for a lamp removal and replacement, the ballast automatically restarts the lamp in the proper manner, maximizing lamp life and minimizing stress on the power MOSFETs or IGBTs.

Half-Bridge Current Sensing and Protection

The third pin used for protection is the CS pin, which is normally connected to a resistor in the source of the lower power MOSFET, as shown in Figure 14.

The CS pin is used to sense fault conditions such as failure of a lamp to strike, over-current during normal operation, hard switching, no load, and operation below resonance. If any one of these conditions is sensed, the fault latch is set, the oscillator is disabled, the gate driver outputs go low, and the chip is put into the micropower mode. The CS pin performs its sensing functions on a cycle-by-cycle basis in order to maximize ballast reliability.

For the over-current, failure-to-strike, and hard switching fault conditions, an externally programmable, positive-going CS+ threshold is enabled at the end of the preheat time. The level of this positive-going threshold is determined by the value of the resistor R_{OC}. The value of the resistor R_{OC} is determined by the following formula:

$$R_{OC} = \frac{V_{CS+}}{50E-6}, \quad \text{or}$$

$$V_{CS+} = 50E-6 \cdot R_{OC}$$

For the under-current and under-resonance conditions, there is a negative-going CS- threshold of 0.2V which is enabled at the onset of the run mode. The sensing of this CS- threshold is synchronized with the falling edge of the LO output.

Figures 15, 16 and 17 are oscillographs of fault conditions. Figure 15 shows a failure of the lamp to strike, Figure 16 shows a hard switching condition and Figure 17 shows an under-current condition.

Recovery from such a fault condition is accomplished by cycling either SD pin or the VCC pin. When a lamp is removed, the SD pin goes high, the fault latch is reset, and the chip is held off in an unlatched state. Lamp replacement causes the SD pin to go low again, reinitiating the startup sequence. The fault latch can also be reset by the undervoltage lockout signal, if VCC falls below the lower undervoltage threshold.
